Abstract—In this paper we will analyze and compare the graph frameworks Galois, Ligra, Polymer, Gemini and Giraph in their performance. All the frameworks will be tested in shared memory and Galois, Gemini and Giraph are tested on a distributed cluster as well. Furthermore we will give some insight on the complexity of writing custom applications based on these frameworks.

Index Terms—graphs, distributed computing, Galois, Ligra, Polymer, Giraph, Gluon

I. INTRODUCTION

This paper makes the following contributions:

II. OVERVIEW OF THE FRAMWORKS

Galois[1] is a general purpose library designed for parallel programming. The Galois system supports fine grain tasks, allows for autonomous, speculative execution of these tasks and grants control over the task scheduling policies to the application. It also simplifies the implementation of parallel applications by providing an implicitly parallel unordered-set iterator.

For graph analytics purposes a topology aware work stealing scheduler, a priority scheduler and a library of scalable data structures have been implemented. Galois includes applications for for many graph analytics problems, among these are single-source shortest-paths (sssp), breath-first-search (bfs) and pagerank. For most of these applications Galois offers a huge amount of algorithms to perform these analytics problems and many setting options, like the amount of threads used or policies for splitting the graph. All of these applications can be executed in shared memory systems and due to the Gluon integration in a distributed environment.

Gluon[2] is a framework written by the Galois team as a middleware to write distributed systems for graph analysis. It reduces the communication overhead needed in distributed by exploiting structural and temporal invariants.

The code of Gluon is embedded into the project of Galois and already integrated with it. It is possible to integrate Gluon with other frameworks too, which the Galois team showed in their paper[2].

Polymer is very similar to Ligra, in fact Polymer inherits the programming interface from Ligra[3].

Polymer aims to minimize both random and remote memory accesses by implementing NUMA- and graph-aware data layout and memory access strategies. Specifically, Polymer co-locates graph data and the computation within NUMA-nodes to reduce remote memory accesses. For example, Polymer

eliminates remote accesses by letting threads allocate memory in their local memory node for graph topology data like vertices and edges that are only accessed by one thread. Application-defined data with static memory locations which gets dynamically updated during computation is allocated with virtual addresses that make for a seamless cross-node data access. Other mutable runtime states (e.g. active vertices) might be dynamically allocated in each iteration. This data is allocated in a distributed way but only accessed through a global lookup table.

III. AND

A. An overview of some graph formats

A rather big portion of our time was invested in figuring out which graph framework requires which graph formats. We thus decided to give an overview over all the formats we encountered, with explanation on how they represent the graph.

Additionally, to make life in the future a little bit easier, we wrote multiple tools to convert graphs acquired from Snap or Konect to the required formats. Additional information on this is available in the section Supplementary Data at the end.

1) *AdjacencyList*: The AdjacencyList and WeightedAdjacencyList formats[4] are used by Ligra and Polymer. They represent the directed edges of a graph as a number of offsets that point to a set of target nodes in the file. First the file contains the number of vertices n and edges m , followed by an offset for each vertex. This offset specifies at what point in the following list of numbers the information for a node begins. Lastly the file format contains a list of target nodes. The numbers are all separated by newlines.

n

m

o_1

o_2

\vdots

o_n

t_1

t_2

\vdots

t_m

The offsets $o_i = k$ and $o_{i+1} = k + j$ mean that vertex i has j outgoing edges, these edges are

$$(i, t_k), (i, t_{k+1}), \dots, (i, t_{k+j-1})$$

For the WeightedAdjacencyList format, the weights are just appended to the end of the file in the same order as the edges.

2) *EdgeList*: The EdgeList format is probably the easiest to understand and is one of the most commonly used in the online graph repositories. The directed edges $(s_1, t_1), (s_2, t_2), \dots$ or $(s_1, t_1, w_1), (s_2, t_2, w_2), \dots$ are represented in the following way.

$$\begin{array}{ccc} s_1 & t_1 & w_1 \\ s_2 & t_2 & w_m \\ \vdots & & \\ s_m & t_m & w_m \end{array}$$

The weights are optional, everything is ASCII encoded and the inline delimiter is a variable amount of any whitespace.

3) *Binary EdgeList*: The binary EdgeList format is used by Gemini. Finding information on this format required reverse engineering of the Gemini code.

We found that Gemini requires the following input format

$$s_1 t_1 w_1 s_2 t_2 w_2 \dots$$

where s_i, t_i have `uint32` data type and the optional weights are `float32`. Gemini will derive the number of edges from the file size, so there is no file header or anything similar allowed.

4) *Giraph's numerous I/O formats*:

IV. OUR TESTING METHODS

A. Hardware and Software

For testing all systems we used 5 machines with 96 CPU cores each (48 physical) and 256 GB of RAM. One of those machines only had 128 GB of RAM, this one was only used as part of the calculation cluster for the distributed systems. All servers were running Ubuntu 19.x. Setup of each framework was performed according to our provided installation guides.

B. Benchmark setup

We measured the total runtime of each process as well as the actual calculation times. The console output of each framework was used as an indicator for when loading the graph data was finished. This proved to be more difficult than expected in some cases.

Each test case consisting of graph, framework and in some cases even the algorithm was run 10 times, allowing us to smooth slight variations in the measured times. This also helps to reduce the error we introduced by measuring time through the console log.

All benchmarks were initiated by our benchmark script that is available in our repository.

We will compare both the computation times as well as the execution times. This way we compare how much setup time each framework has.

V. RESULTS

A. Komplexität Aufsetzen

B. Komplexität eigene Apps schreiben

C. Pure Performance-Ergebnisse

D. Ergebnisse Calc time

der offensichtliche, wichtige Vergleich

E. Ergebnisse exec time

hier erhoffe ich mir einen Vergleich der Ladezeiten und erwarte, dass Systeme wie Giraph, die erstmal auf irgendwas warten schlecht abschneiden. Aber vielleicht ist auch die setup time bei gleichen frameworks zwischen verteilt und shared memory ganz interessant zu vergleichen.

VI. DISCUSSION

VII. CONCLUSION

The conclusion goes here.

ACKNOWLEDGMENT

We are using the graph frameworks Galois [1], Ligra [5], Polymer [3], Gemini [6] as well as Apache Giraph [7].

Also we use Gluon [2] for the distributed setups.

Gemini [6]
